

Insights into Breast Cancer from deconvolution of bulk RNA Sequencing Data

By Yves Greatti, Reem Shamma, and Lingzhu Shen

Abstract

Computational methods to deconvolve cell-type composition in bulk RNA sequencing data provide insights into potential molecular mechanisms underlying cancer development and progression. Deconvolution of the Cancer Genome Atlas (TCGA) breast cancer (BRCA) dataset revealed heterogeneity in cell-type and subtype proportions across individuals diagnosed with BRCA, which qualitatively differed from control individuals. Applying machine learning shows that monocytes, natural killer (NK) and natural killer T (NKT) immune cells most significantly impact immune response. Pathway analyses revealed differential pathway activity across immune cell types. The density of multiple immune cell types is associated with either a significant increase or decrease in BRCA patient survival, revealing the complex role of the immune response in tumor progression. More research into how differences in immune cell composition impact BRCA development and progression may enhance diagnostic and therapeutic strategies.

Introduction

Cancer cells produce cytokines and chemokines that attract a diverse population of immune cells, including macrophages, neutrophils, and lymphocytes. The impact of these tumor-infiltrating immune cells is a topic of debate. Some groups show that tumor-infiltrating immune cells may physically destroy tumor cells, thereby reducing tumor burden and improving clinical prognosis [8]. However, persistent activation of the immune system and failure of the inflammatory response to resolve may lead to chronic inflammation, which promotes tumor growth [7]. This inflammation stimulates genomic instability, triggers epigenetic modifications, and upregulation of cancer anti-apoptotic pathways, underscoring the potential mechanisms by which inflammation contributes to tumor growth and possibly metastasis [10].

Recent studies have shown that accounting for the heterogeneity of immune cell infiltration can result in more sensitive survival analyses and more accurate tumor subtype predictions [3,4]. Ongoing research focuses on the role of infiltrating lymphocytes and other immune cells in the tumor microenvironment (TME). Myeloid cells like macrophages, monocytes, dendritic cells, neutrophils, basophils, and eosinophils are often found in various tumor tissues. In malignant tumors, levels of infiltrating immune cells are associated with tumor growth and cancer progression [5, 6].

Bulk RNA sequencing measures the average gene expression across all cells within a sample and cannot distinguish between different cell types or states. On the other hand, single-cell RNA sequencing (scRNA-seq) enables researchers to identify and profile the transcriptome of individual cells, allowing for the characterization of cell types and their heterogeneity within a sample. By comparing bulk RNA expression data to scRNA-seq data from the same or similar tissues, deconvolution algorithms estimate the proportions of different cell types present in bulk samples. This approach may circumvent costly and labor-intensive scRNA-seq experiments, while still providing rich data.

Breast cancer (BRCA) is one of the most common cancers among women worldwide. Despite advances in treatment, the prognosis for patients with BRCA remains highly variable. Recent studies have demonstrated that the heterogeneity of tumor cells and the TME can significantly impact patient outcomes, with greater heterogeneity corresponding to less immune cell infiltration, less activation of the immune response, and worse survival in breast cancer [9]. Identifying the cell-type-specific molecular mechanisms is needed to improve our understanding of the development and progression of BRCA tumors, and ultimately enhance diagnostic and therapeutic strategies.

The molecular subtypes of breast cancer depend on the genes the cancer cells express. There are four main molecular subtypes of invasive breast cancer. Luminal A breast cancer consists of cancer cells that are estrogen receptor (ER)-positive and progesterone receptor-positive, human epidermal growth factor receptor 2 (HER2) negative and express low levels of the protein Ki-67. Luminal B breast cancer is estrogen receptor-positive, HER2-negative, and either has elevated levels of Ki-67 or is progesterone receptor-negative. HER2-enriched breast cancer is estrogen receptor-negative, progesterone receptor-negative, and HER2-positive. Finally, triple-negative breast cancer (TNBC) or basal-like breast cancer lacks estrogen and progesterone receptors, lacks HER2 expression, is more prevalent in individuals with a BRCA1 mutation, and is the most aggressive subtype.

In this study, we attempt to characterize the TME's immune cell composition. We find that individuals diagnosed with BRCA have a high density of cycling T-cells and macrophages, while control individuals show prominent levels of hormone sensing (HS), basal (BA), and alveolar (AV) cells. Immune scores, which quantitatively estimate immune cells' impact on the immune response, were most significant in monocytes, NK, and NKT cells. The Transforming Growth Factor (TGF)- β pathway was significantly activated across almost all immune cell types in BRCA patients, while the TNF-related apoptosis-inducing ligand (TRAIL) pathway and Mitogen-activated protein kinase (MAPK) had reduced activity. Finally, density of immune cells differentially impacted survival, with elevated levels of memory B cells correlating with significantly lower overall survival and significantly higher disease-free survival (DFS), and the density of NKT cells inversely correlating with DFS.

Methods

The population data for this study was sourced from TCGA project, a collaborative effort between the National Cancer Institute (NCI) and the National Human Genome Research Institute (NHGRI) to systematically analyze and catalog genomic and molecular data from several types of cancer. The TCGA data on BRCA includes information on DNA mutations, gene expression, epigenetic changes such as DNA methylation, and clinical data related to cancer survival and demographics. The TCGA-BRCA project consists of data from 1,111 cancer patients and 113 disease-free control patients.

RNA sequence data selected for this study was of the "Primary" and "Solid Tissue Normal" categories. Since MuSiC2 performs its own normalization, unstranded data was only considered and *TPM normalized* data were disregarded. The median age of the cohort was 58 years, and most patients were white (75.6%). The two most common subtypes of BRCA were BRCA_LumA (50.9%) and BRCA_LumB (20.1%), with most patients at stage IIA (32.9%), stage IIB (23.6%), and stage IIIA (14.4%) (Table 1). Data was collected using TCGAbiolinks and TCGAWorkflow packages in R. To ensure consistency across the data, the ENSEMBL Id genes present in the TCGA dataset were converted into gene symbols using the genomic centric EnsDb.Hsapiens.v79 package. Any genes that were unresolved or duplicated were subsequently removed from the expression count matrix, to prevent any discrepancies or confounding factors in the downstream analysis.

For scRNA-seq data, two studies and their datasets were considered:

- Wu et al. (GSE176078) provided a more detailed understanding of the cellular and molecular heterogeneity within breast tumors [11]. The researchers performed scRNA-Seq (Chromium, 10X Genomics) on 26 primary tumors from three major subtypes of breast cancer (11 ER+, 5 HER2+, and 10 TNBC) and identified 9 major cell types, 29 minor cell types and 49 cell subtypes (Table 2). The study also found that macrophages with high expression of fatty acid metabolic genes FABP5 (LAM1), as well as macrophages that clustered around high levels of CXC chemokines 10 (CXCL10-hi) are key sources of immunosuppressive molecules within the human breast TME. Spatial analysis revealed the proximity of these macrophages to lymphocytes expressing programmed cell death 1 protein (PD-1+ lymphocytes).
- The second study and its corresponding dataset, Pal et al. (GSE161529), presents an extensive single-cell transcriptome map of over 430,000 cells (Table 3), from 52 patients [12]. They obtained the samples under various conditions including different hormonal stages, preneoplastic BRCA1+/- tissue, different cancer subtypes (4 TNBCs, 4 BRCA1 TNBCs, 6 HER+ tumors), as well as matching tumor and involved axillary lymph node pairs. The data was downloaded using the GEOquery package.

Our study also aimed to determine the impact of various immune cell types on the immune response. To do this, we utilized *ESTIMATE* immune scores for TCGA BRCA patients and cross-validated our findings using an *XGBoost* regression model with optimized hyperparameters via the *XGBoost* Python API. Specifically, we trained the model on 75% of the available data and assessed its performance on the remaining 25%. The independent variables were the immune cell type proportions of the different TCGA tumor samples obtained by deconvolution and the outcome variable was the immune score for this patient as provided by the *ESTIMATE* R package. Cross-validation of the model and careful tuning of its parameters and using *SHAP* python package methods provided some insight into the importance of each immune cell type of the immune score.

To identify oncogenes from the estimated cell proportions we used the *PROGENy* R package, and the Python package, *decoupler*. *PROGENy*, performs gene set enrichment analysis (GSEA) and pathway analysis of gene expression data. The *decoupler* Python package utilizes statistical methods such as Weighed Sum (WMEAN) or Univariate Linear Model (ULM) and a prior knowledge on gene regulatory networks to predict the activity of transcription factors and pathways within a sample population.

We then investigated the potential correlation between cellular fractions and clinical outcomes in the TCGA BRCA cohort. To this end, we conducted survival analyses using TCGA clinical data obtained through the cBioPortal and the cBioPortalData R package. Specifically, we utilized a median-point strategy to divide patients into low and high cell type proportions. We then performed Kaplan-Meier survival analyses with a log-rank test using a Cox's proportional-hazard model from the Python package, *lifelines*. We also computed the hazard ratio with a 95% confidence interval and corresponding p-values, and generated Kaplan-Meier curves using the Kaplan Meier Estimator function in the Python package, *scikit-survival*. Overall, these analyses allowed us to assess any potential associations between cellular alterations and clinical outcomes, including overall survival (OS) and disease-free survival (DFS) of patients in the TCGA BRCA cohort.

Results

Deconvolution of Immune Cells From RNA-Seq Data

Using MuSiC2 for single-cell deconvolution, we were able to estimate the proportions of different immune cell subpopulations within each patient's tumor.

We used scRNA-seq data of normal individuals from GSE1611529 to deconvolute the bulk RNA seq data from the 113 disease-free control patients of the TCGA BRCA cohort. Analysis revealed that the disease-free control patients in our cohort had high proportions of HS, AV, and vascular and lymphatic cells (Fig. 1B), which is consistent with what was observed in normal GSE1611529 patients (Fig. 1A). While a statistical test such as MannWhitney-U comparing the two cohorts'

cell type proportions would not return a meaningful result due to the small sample size of only 4 normal patients, these visual findings provide a rough validation of our method.

Figure 1: Cell type proportions from single-cell deconvolution using MuSiC2 of normal patients. **Fig 1A.** Cell type proportions from four individuals from the GSE1611529 dataset (top). **Fig 1B.** Cell types of normal patients in our TCGA BRCA cohort deconvoluted using GSE1611529 (bottom).

In GSE17078 tumor patients, a significant presence of immune cells, such as macrophages, monocytes, and T cells (CD4+ and CD8+), was observed, with similar proportions found in the deconvolution output of TCGA breast cancer patients (Fig. 2A, and table 1 and 2 in appendix). However, upon excluding the most overrepresented cell types, macrophages and non-immune cells, the adjusted ratios allowed us to observe a substantial amount of NK and NKT cells, as well as memory B cells to a lesser extent (Fig. 2B-C). These findings highlight the complex and diverse nature of the immune cell composition within breast cancer tumors.

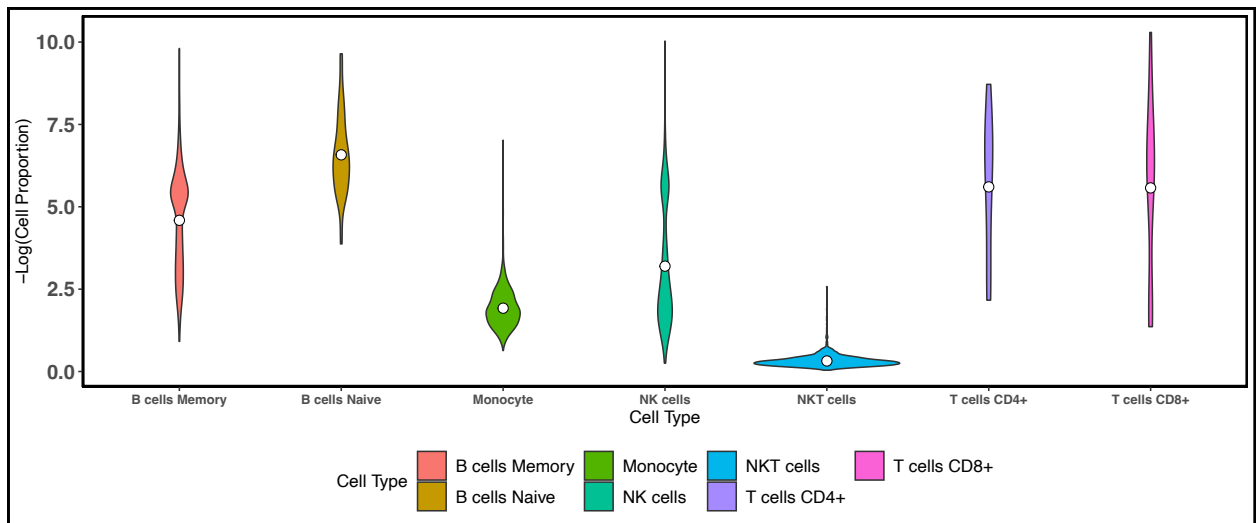

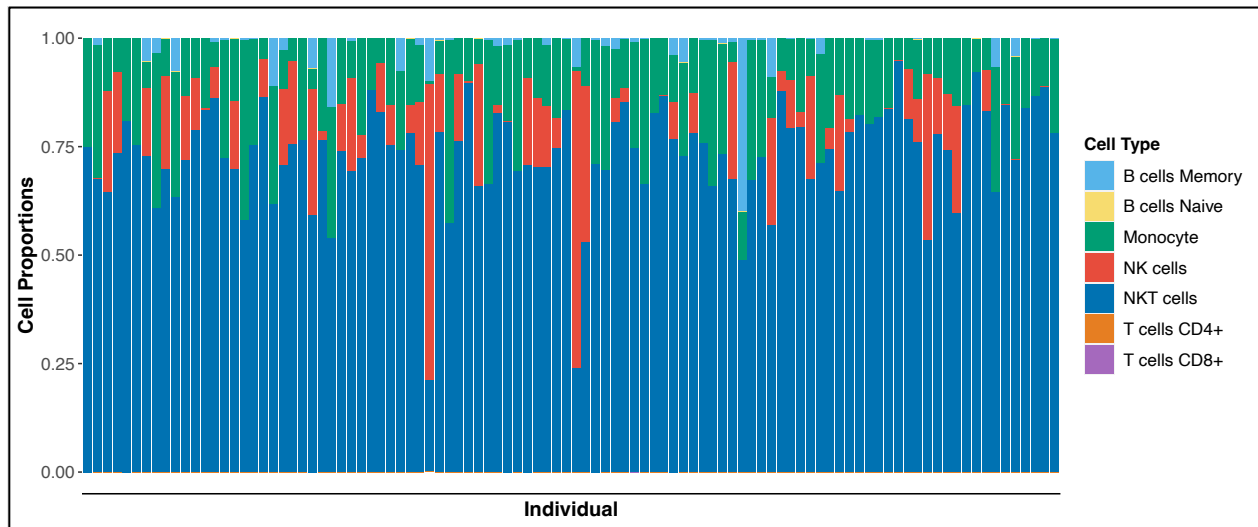

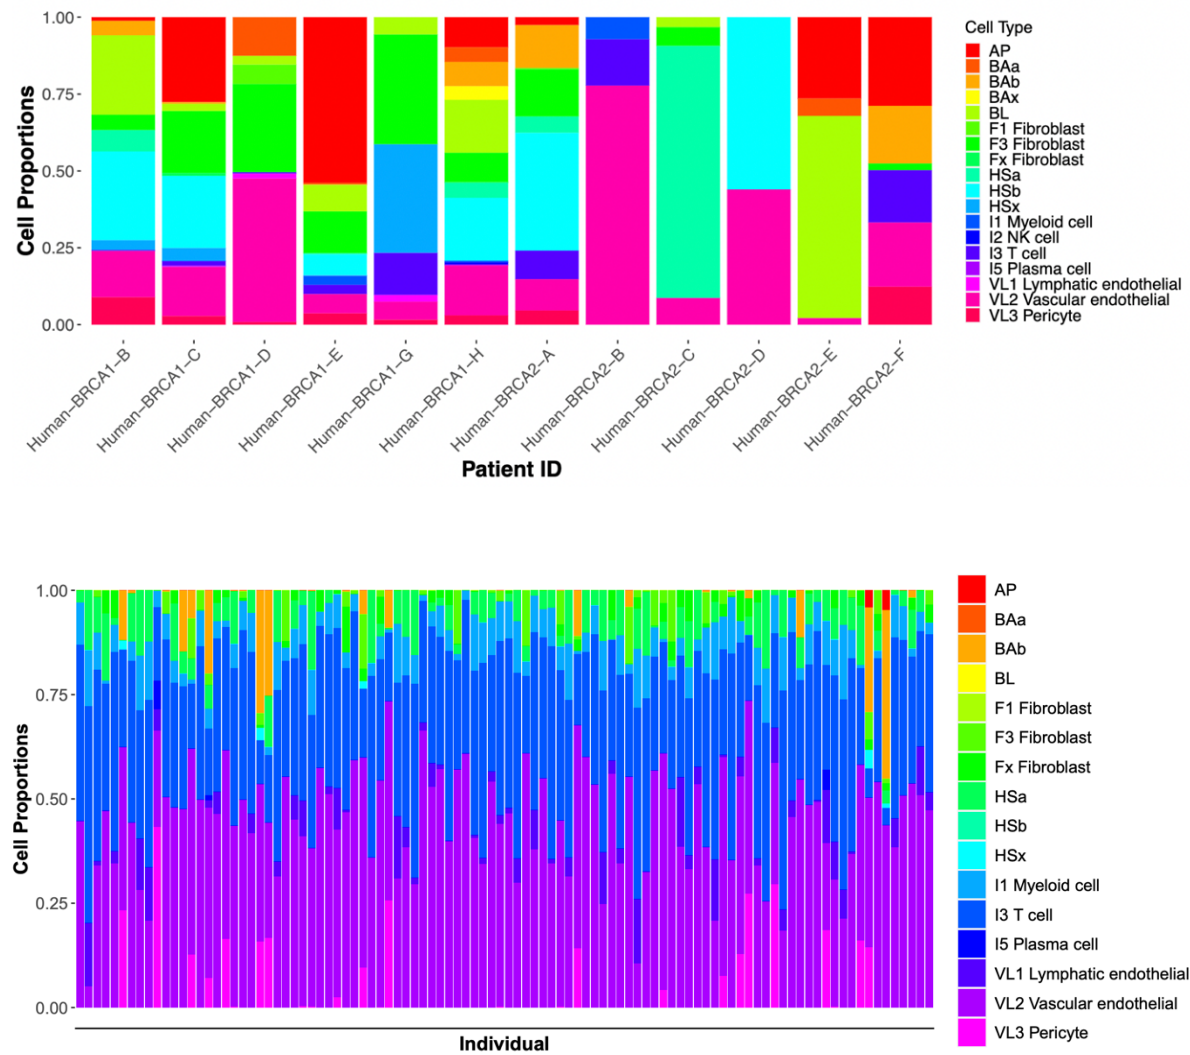

Figure 2: Cell type proportions from single-cell deconvolution using MuSiC2 of tumor patients.

Fig 2A. Cell type proportions of tumor patients in the TCGA BRA cohort before excluding overrepresented cell types (top). **Fig 2B-C.** Cell type proportions in TCGA BRA cohort after excluding overrepresented cell types as stacked bar plots (middle) and violin plot (bottom).

The same MuSiC2 deconvolution technique was applied to analyze cell subtypes in tumor patients. The VL2 vascular endothelial and immune I3 T cell subtypes were predominant in both GSE161529 (Fig 3A) and TCGA (Fig. 3B) cancer patients, although their median levels were lower compared to other cell subtypes such as HSa, HSx, and BL (Fig 3C).

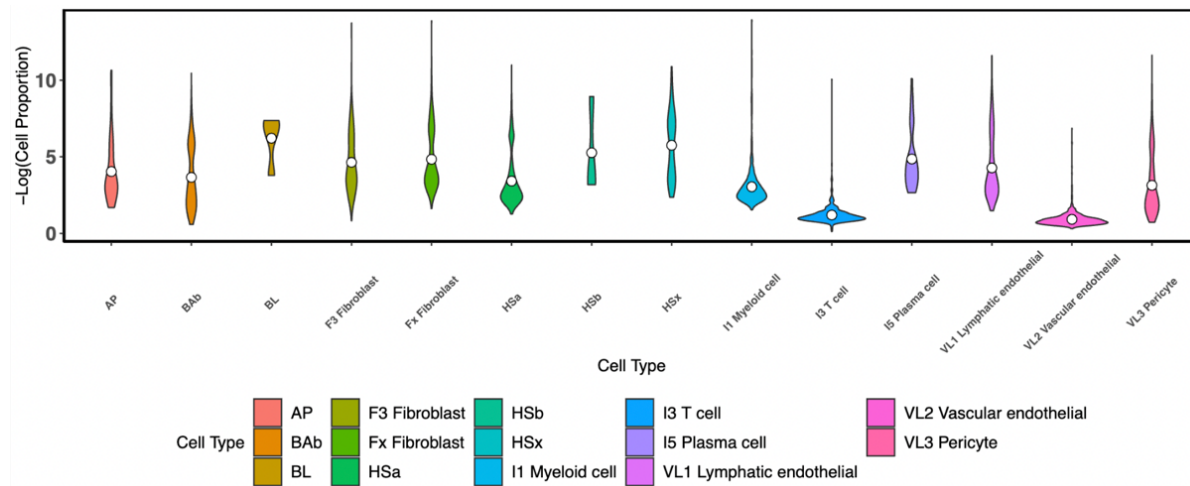

Figure 3: Cell subtype proportions from single-cell deconvolution using MUSiC2 of BRCA patients. **Fig 3A.** Cell subtypes of BRCA tumor patients from scRNA seq data of GSE161529. **Fig 3B-C.** TCGA BRCA cohort cell subtype proportions represented as stacked bar chart (middle) and violin plot (bottom) across individuals.

When computing the proportions of immune cells only (T cells, myeloid cells, and plasma cells) among the TCGA BRCA cohort, we found that T cells constituted most immune cells (Fig. 4).

Figure 4: Immune cell proportions in TCGA BRA cohort.

These results suggest that while some immune cell subtypes are more prominent in breast cancer tumors, there is still significant heterogeneity in the immune cell composition across tumors.

Evaluation of Immune Cells in the Immune Response

Immune scores quantitatively measure the impact of immune cells on the immune response. Most of the ESTIMATE immune score distribution is similar between normal and tumor patient (Mann-Whitney-U test, $p\text{-val}=0.556$). However, some tumor patients have higher absolute immune scores compared to normal patients.

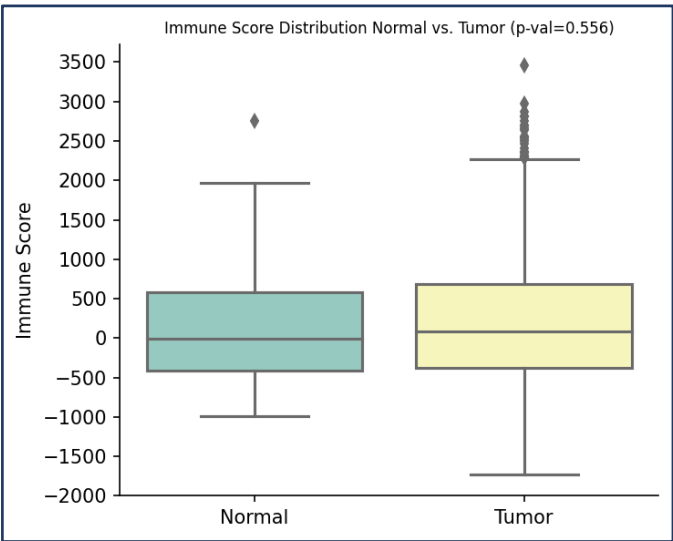

Figure 5: Immune score distribution across normal and tumor patients.

After obtaining immune cell type proportions by deconvolution using MuSiC2, we developed a decision-tree based regression model ($R^2 = 0.647$, RMSE = 494.589) to predict the ESTIMATE immune score of the tumor patients. To determine the influence of each cell type on the immune score, we calculated the model coefficients and their p-values (Table 1). Higher proportions of CD8+ T cells and NKT cells reduce the immune score, indicating that they contribute less to immune response, while higher proportions of monocytes and NK cells increase immune scores and have a higher impact on immune response.

Additionally, we utilized Shapley values to estimate the contribution of each cell type to the immune system. Our findings revealed that monocytes, NK, and NKT cells were the most impactful contributors to the immune score among tumor patients (Figure 6).

Cell Type	Coefficient	P-value
B Cell Memory	2.773	0.728
B cells Naive	20.458	0.167
T cells CD8+	-106.369	< 0.001

T cells CD4+	42.236	0.230
NK cells	25.289	0.007
NKT cells	-744.481	< 0.001
Monocytes	1155.076	< 0.001

Figure 6: Distribution of mean absolute of SHAP values for each immune cell type.

Pathway Analysis across cell types in normal and BRCA patients

Within the context of the 14 cancer pathways investigated in our study, immune cells including B, T, and NK cells exhibited a trend of higher activity in pathways that regulate immune responses, such as TGF- β , but lower activity in pathways that induce apoptosis, such as TRAIL. Immune cells also show a significant reduction in the activity of the MAPK pathway, which is known to promote cell growth and proliferation (Fig. 7).

Each gene in PROGENy pathway has a weight representing its level within a given pathway (Appx. Table 3). Sorting these genes by weight shows that ID1, ID3, COM, PMEPA1, SMAD7 in the TGF- β pathway and RHEBL1, SMIM3, GPR18, RAB37, RNF175 in the TRAIL pathway are potential prognostic markers in different cancers. Similar correlations were found with the immune cell type proportions obtained from GSE161529 data deconvolution (Figure 7: middle and bottom plots, and Appx. Figure 2). Interestingly the same immune cell types in normal patients show higher activity in the Hypoxia pathway compared to tumor patients.

These observations highlight the multifaceted role of immune cells in cancer development and underscore the importance of considering the functional activity of these cells in the context of cancer pathways.

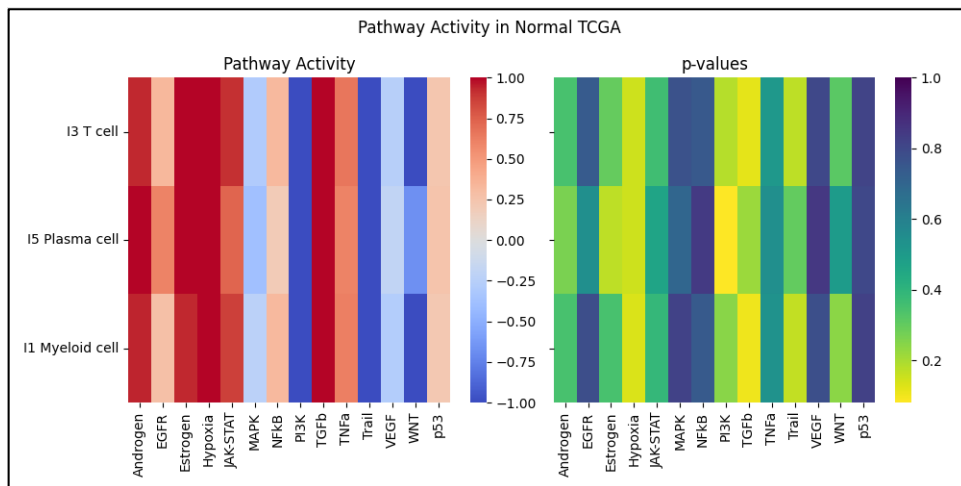

Figure 7: Pathway inference performed on the TCGA BRCA cohorts using the results obtained from deconvolution analysis (top). Immune cell activity levels across different pathways for TCGA normal and tumor patients (middle and bottom).

Correlation between cell type and clinical outcomes

To investigate potential clinical implications of differences in immune cell type and subtype proportions, we conducted an analysis of overall survival (OS) and disease-free survival (DFS) of the tumor patients in our BRCA TCGA cohort showing varying levels of cell type/subtypes.

Our analysis of the BRCA TCGA cohort with deconvolution using GSE177078 suggests that tumor patients with elevated levels of memory B cells had significantly lower OS and significantly higher DFS when compared to patients with low levels of memory B cells (Fig. 8). Significant differences in survival were not observed for varying levels of naïve B cells (Fig. 8). High levels of CD8+ T cells showed lower DFS that was near significant ($p\text{-val} = 0.07$) (Fig. 9). Similarly, elevated levels of NKT cells had significantly lower DFS, while low levels of NKT cells showed higher OS that was near significant ($p\text{-val} = 0.06$) (Fig. 10).

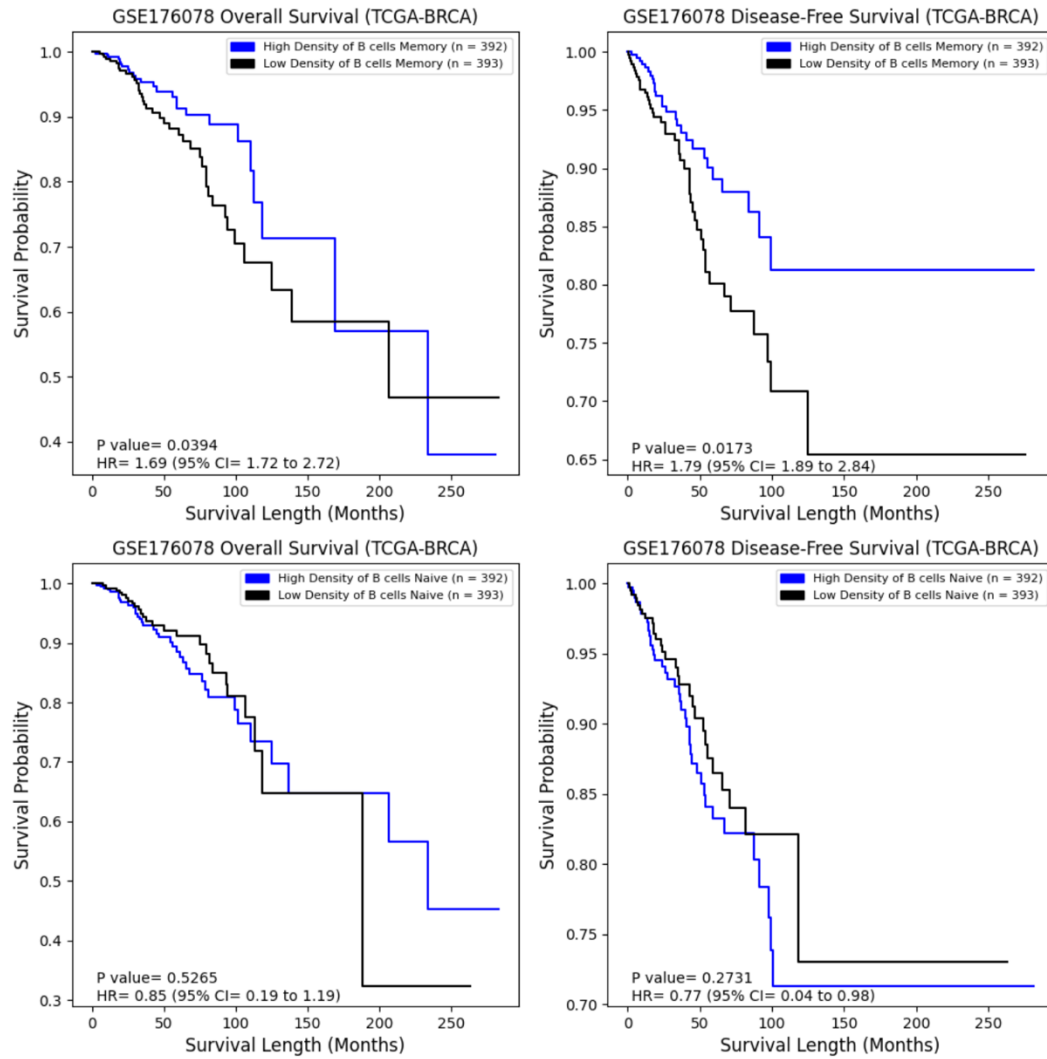

Figure 8: Difference in overall survival (left panels) and disease-free survival (right panels) across TCGA BRCA tumor patients (deconvoluted via GSE176078) showing various levels of memory B cells (top) and naïve B cells (bottom).

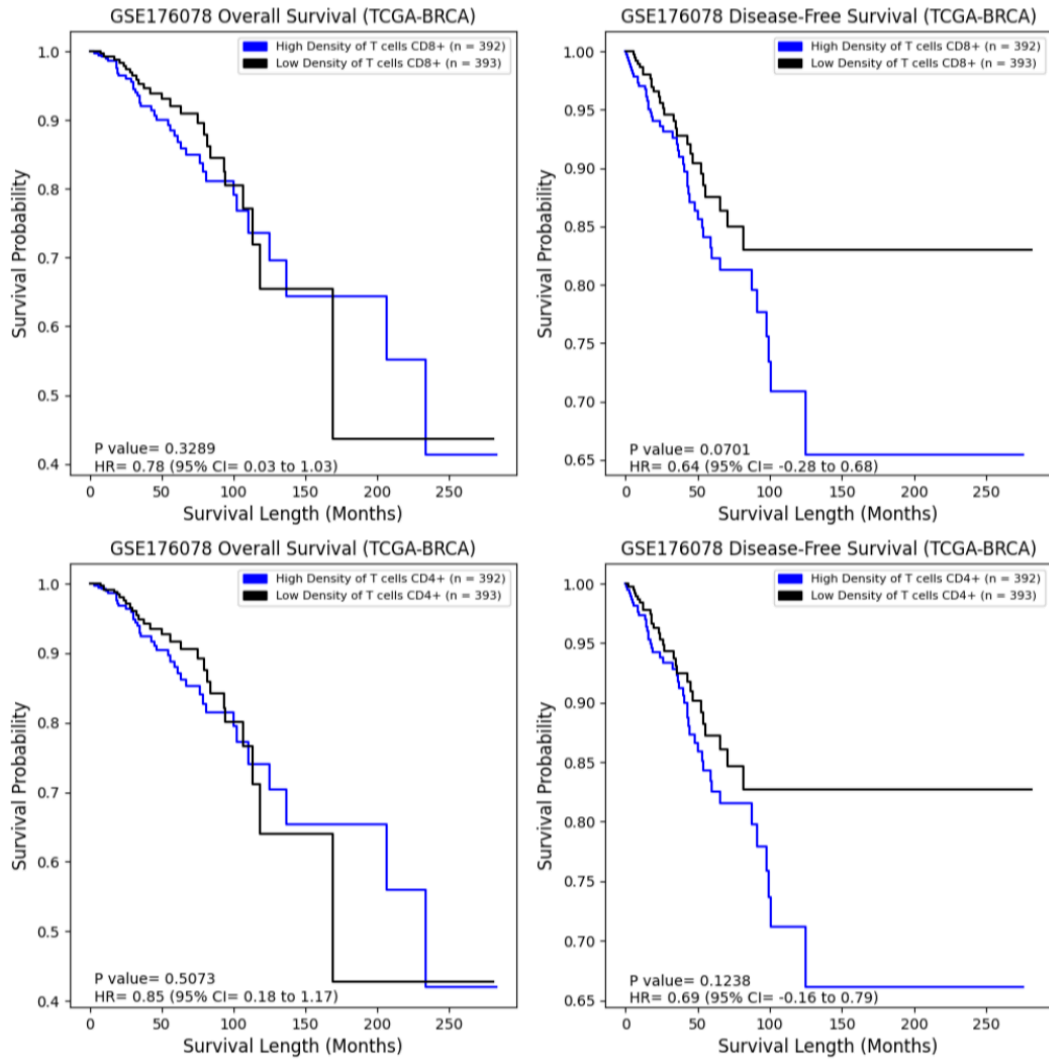

Figure 9: Difference in overall survival (left panels) and disease-free survival (right panels) across TCGA BRCA tumor patients (deconvoluted via GSE176078) showing various levels of CD8+ T cells (top) and CD4+ T cells (bottom).

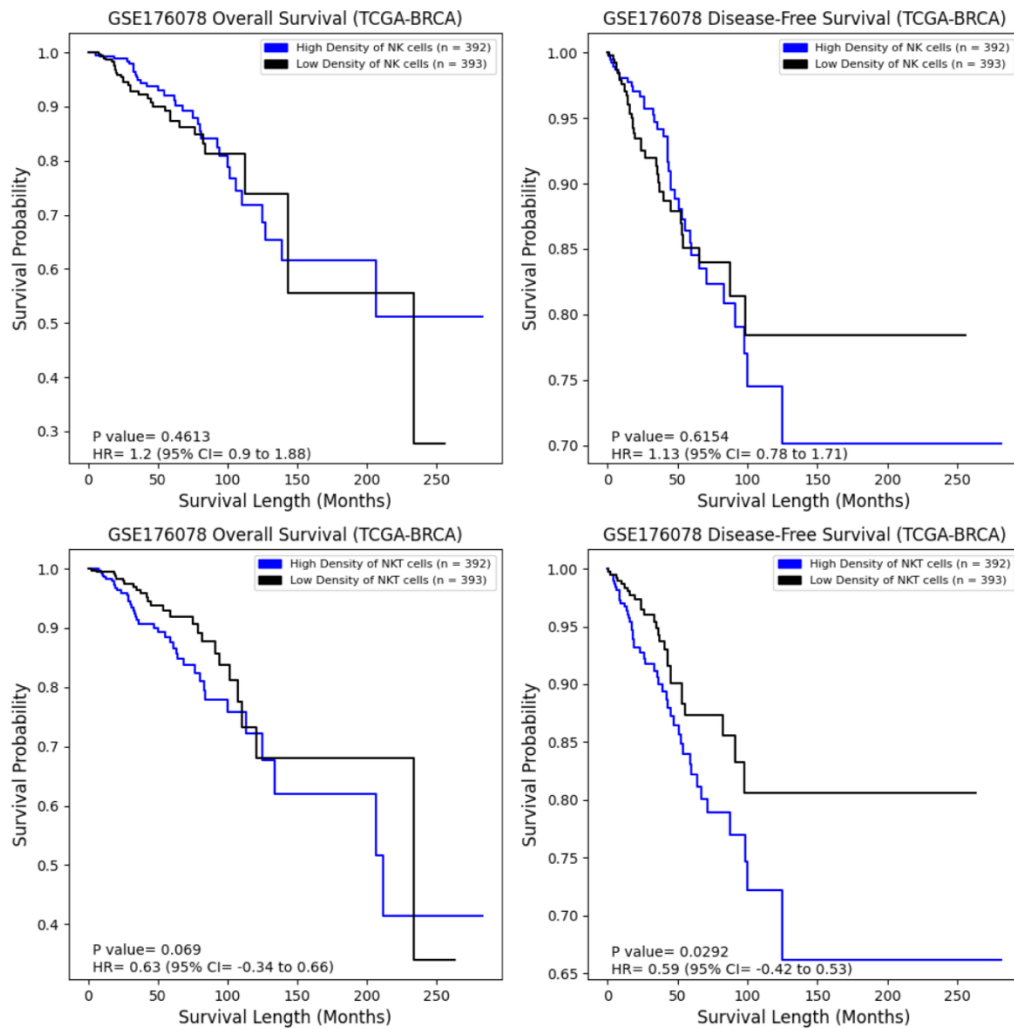

Figure 10: Difference in overall survival (left panels) and disease-free survival (right panels) across TCGA BRCA tumor patients (deconvoluted via GSE176078) showing various levels of NK cells (top) and NKT cells (bottom).

Interestingly, we did not observe significant differences in OS and DFS across varying levels of immune cells when conducting the same analysis using the GSE161529 dataset (Appx. Figure 1). Additionally, we found that differences in levels of vascular, lymphatic, and alveolar cells did not significantly impact survival outcomes in GSE161529 (Appx. Figure 1). These results provide insight into the potential prognostic value of specific immune cell subpopulations in BRCA patients and underscore the importance of considering heterogeneity in immune cell composition when assessing clinical outcomes.

Discussion

In the following study, we used the MuSiC2 deconvolution algorithm to interpret a myriad of bulk RNA-seq data sampled from both tumor and normal/control patients in the TCGA BRCA cohort of patients, utilizing two sc-RNA seq datasets. The MuSiC2 iterative algorithm assumes that when using bulk and single-cell reference samples from different clinical conditions, most cell-type-specific gene expression patterns remain consistent across both. Therefore, isolating the few genes that show cell-type-specific differential expression between different clinical conditions in the scRNA reference datasets allows for accurate cell-type proportion estimates [2].

Our deconvolution provides insight into the heterogeneous population of cell types and subtypes across the normal and tumor bulk RNA samples. Cells that maintain the homeostatic functioning of breast tissue were most populous in normal individuals. For example, the hormone-sensing hormone receptor (HR+) cells in the luminal layer of epithelial ducts express steroid hormone receptors for estrogen, progesterone, and prolactin, allowing them to participate in dynamic signaling pathways [13]. Meanwhile, BA cells in the outer basal layer of mammary glands have contractile features, allowing the movement of milk through the breast during lactation [14].

The relative proportion of immune cells was much higher in BRCA patients compared to normal patients. This is consistent with previous studies showing that the composition of immune cells in breast tissues progressively increases from normal to breast cancer [17]. Cycling T-cells and macrophages predominated (Fig. 2), which is also consistent with literature findings [19]. T-cells are the most effective at triggering adaptive anti-tumor responses, although T-cell subtypes play varying roles [19]. CD8+ T cells are known to produce IL2 and IFN γ involved in tumor elimination, and their presence is associated with good prognosis [19], although our findings did not support this (Fig. 6). CD4+ T cells produce a different subset of ILs, including IL4, IL5, IL13 IL21 and IL2, that correlate with tissue inflammation and have pro-tumor effects. This is consistent with the trend observed in our DFS analysis of CD4+ cells (Fig. 9), although our results were not statistically significant (p-val = 0.507). Macrophages are involved in tumor-associated inflammation, with a higher abundance of macrophages corresponding to poor prognosis. Cancer cells secreting colony-stimulating factor (CSF)-1 recruit tumor-associated macrophages that release epidermal growth factors (EGFs), modifying cancer cells to increase their migration and metastasis [19].

Our pathway analysis showed a significant upregulation of the TGF- β pathway across all immune cell types in deconvoluted tumor samples of the TCGA BRCA cohort (Fig. 7). In T-cells, TGF- β inhibits the expression of transcription factors needed in T-cell differentiation, exerting antiproliferative effects on T-cells [21]. Within the broader TME, high TGF- β expression is known to suppress the anti-tumor responses of Type 1 T helper cells [22]. TGF- β pathway activity blocks NK function in several different ways, including silencing NK surface receptors

that facilitate recognition of stressed and transformed cells, or influencing NK differentiation to remove its cytotoxic activity [22]. The WNT pathway was downregulated in normal samples. High WNT activity keeps peripheral T-cells in a more undifferentiated (i.e., proliferative) state and enhances their motility and migration [23]. This is consistent with our observations of higher T-cell proportions in tumor samples (Fig. 2, Appx. Table 1). Finally, MAPK activity was reduced in BRCA. The MAPK pathway increases the production of several inflammatory mediators, including the tumor-necrosis factor (TNF), IL-1 β and IL-6 [24].

Our survival analysis across BRCA patients with high versus low-density of immune cells showed conflicting results. In some cases, higher levels of immune cells (i.e., memory B cells) had a reduced probability of overall survival (OS), but an increased probability of disease-free survival (DFS) (Fig. 8). Meanwhile, high levels of NKT were associated with a significant reduction in DFS and a nearly significant increase in OS probability (Fig.10). These contradictions might represent the two opposing faces of the immune system's role in tumor development. The immune system might prevent and control tumor progression through immunosurveillance, in which immune cells recognize and destroy cancer precursor cells [15, 16]. However, the immune system might also facilitate cancer progression through tumor-associated inflammation [7]. Particularly, B cells have been shown to have both positive and negative roles across different cancer types including BRCA; B cells may have anti-tumor effects by increasing T-cell functionality, thereby having favorable prognosis, but higher levels of B cells are also associated with worse prognosis in other studies [19,20]. Similarly, NK cells can have anti-tumor responses by releasing cytolytic granules that target and kill cancer cells, and by producing chemokines and cytokines that enhance the adaptive immune system's ability to target tumors. However, the types of tumor-related soluble factors in the microenvironment (e.g., IL-10) produced by different tumor-infiltrating immune cells (e.g., macrophage), may negatively affect NK cells' activity [19].

Conclusion

Our study utilized a deconvolution algorithm to analyze bulk RNA-seq data from the TCGA BRCA cohort and identified cell-type-specific gene expression signatures associated with patient survival. We observed that HS, BA, and AV cells are the most populous cell types in normal vs. control individuals, while the relative proportion of immune cells increases in BRCA patients. Cycling T-cells and macrophages are the predominant immune cell types in BRCA tumors. Pathway analysis reveals significant upregulation of the TGF- β pathway across all immune cell types. Our survival analysis showed conflicting results, suggesting opposing roles of the immune system in tumor development. Overall, our study provides insights into the heterogeneous population of cell types and subtypes present in breast tumors, informs their potential roles in cancer-related pathways, and highlights the need for further research into the complex interactions between immune cells and cancer cells in the TME.

Future Work

One limitation of our study is that the TCGA BRCA cohort pooled several different classes of BRCA together. The heterogeneity of immune cell compositions varies across cancer subtypes and even across individuals with the same cancer subtype [17, 18]. This heterogeneity creates a challenge in developing effective immunotherapies that restore and elicit anti-tumor immune responses by modulating specific tumor cells or antibodies. Diagnostic tools that evaluate patients through a more personalized-medicine approach might allow physicians to predict immunotherapy treatment responses per individual. Single-cell analyses such as that used in this study may improve our understanding of interactions between tumor and immune cells in the TME and subsequently allow us to develop new drug targets for patients who do not respond to current immunotherapies [17, 25, 26].

Another limitation of our deconvolution approach in its potential clinical utility is that it does not provide information on the spatial distribution of immune cells within breast tissues. In normal breast tissue, both innate (e.g., NK cells) and adaptive (e.g., CD8+ and CD4+) immune cells are primarily present in epithelial tissues of breast ductal lobules. Throughout cancer progression, these same immune cell types, along with B cells and macrophages infiltrate the tumor parenchyma and stroma [17]. Therefore, coupling our single-cell deconvolution technique, which provides a quantitative measure of immune cell proportions, with histological analyses or molecular imaging that show the spatial distribution of cells, may provide a more comprehensive image of the unique TME composition of each patient, helping tailor individual treatment plans.
